

Package ‘RIttools’

July 21, 2025

Version 0.3-5

Title Randomization Inference Tools

Description Tools for randomization-based inference. Current focus is on the d^2 omnibus test of differences of means following Hansen and Bowers (2008) <doi:10.1214/08-STS254> . This test is useful for assessing balance in matched observational studies or for analysis of outcomes in block-randomized experiments.

balanceplot	<i>Create a plot of the balance on variables across different stratifications.</i>
-------------	--

Description

This plotting function summarizes variable by stratification matrices. For each variable (a row in the x argument), the values are under each stratification (the columns of x) plotted on the same line.

Usage

```
balanceplot(
  x,
  ordered = FALSE,
  segments = TRUE,
  colors = "black",
  shapes = c(15, 16, 17, 18, 0, 1, 10, 12, 13, 14),
  segments.args = list(col = "grey"),
  points.args = list(cex = 1),
  xlab = "Balance",
  xrange = NULL,
  groups = NULL,
  tiptext = NULL,
  include.legend = TRUE,
```

```

    legend.title = NULL,
    plotfun = .balanceplot,
    ...
)

```

Arguments

<code>x</code>	A matrix of variables (rows) by strata (columns).
<code>ordered</code>	Should the variables be ordered from most to least imbalance on the first statistic?
<code>segments</code>	Should lines be drawn between points for each variable?
<code>colors</code>	Either a vector or a matrix of shape indicators suitable to use as a <code>col</code> argument to the <code>points</code> function. If the argument is a vector, the length should be the same as the number of columns in <code>x</code> . If the argument is a matrix, it should have the same dims as <code>x</code> .
<code>shapes</code>	Either a vector or a matrix of shape indicators suitable to use as a <code>pch</code> argument to the <code>points</code> function. If the argument is a vector, the length should be the same as the number of columns in <code>x</code> . If the argument is a matrix, it should have the same dims as <code>x</code> . <!-- The suggested vector has been selected to work with RSVGTipsDevice tool tips.-->
<code>segments.args</code>	A list of arguments to pass to the <code>segments</code> function.
<code>points.args</code>	A list of arguments to pass to the <code>points</code> function.
<code>xlab</code>	The label of the x-axis of the plot.
<code>xrange</code>	The range of x-axis. By default, it is 1.25 times the range of <code>x</code> .
<code>groups</code>	A factor that indicates the group of each row in <code>x</code> . Groups are printed under a common header.
<code>tiptext</code>	ignored (legacy argument retained for internal reasons) <!-- If you are using the RSVGTipsDevice library for rendering, you can include an array of the dimensions of <code>x</code> with another dimension of length 2. For example, if there are 4 observations and 2 strata, the array should be 4 by 2 by 2. The <code>tiptext[i, j, 1]</code> entry will be the first line of the tool tip for the data in <code>x[i, j]</code> . Likewise for the second row of the tool tip. -->
<code>include.legend</code>	Should a legend be included?
<code>legend.title</code>	An optional title to attach to the legend.
<code>plotfun</code>	Function to do the plotting; defaults to <code>[R]tools:::.balanceplot</code>
<code>...</code>	Additional arguments to pass to <code>plot.default</code> .

Details

It is conventional to standardize the differences to common scale (e.g. z-scores), but this is not required. When `ordered` is set to true, plotting will automatically order the data from largest imbalance to smallest based on the first column of `x`.

You can fine tune the colors and shapes with the like named arguments. Any other arguments to the `points` function can be passed in a list as `points.args`. Likewise, you can fine tune the segments between points with `segments.args`.

Value

Returns NULL, displays plot

See Also

[plot.xbal](#), [xBalance](#), [segments](#), [points](#)

Examples

```
set.seed(20121204)

# generate some balance data
nvars <- 10
varnames <- paste("V", letters[1:nvars])

balance_data <- matrix(c(rnorm(n = nvars, mean = 1, sd = 0.5),
                        rnorm(n = nvars, mean = 0, sd = 0.5)),
                      ncol = 2)

colnames(balance_data) <- c("Before Adjustment", "After Matching")

rownames(balance_data) <- varnames

balanceplot(balance_data,
            colors = c("red", "green"),
            xlab = "Balance Before/After Matching")

# base R graphics are allowed

abline(v = colMeans(balance_data), lty = 3, col = "grey")
```

balanceTest

Standardized Differences for Stratified Comparisons

Description

Covariate balance, with treatment/covariate association tests

Usage

```
balanceTest(
  fmla,
  data,
  strata = NULL,
  unit.weights,
  stratum.weights = harmonic_times_mean_weight,
  subset,
  include.NA.flags = TRUE,
```

```

    covariate.scales = setNames(numeric(0), character(0)),
    post.alignment.transform = NULL,
    inferentials.calculator = HB08,
    p.adjust.method = "holm"
)

```

Arguments

<code>fm1a</code>	A formula containing an indicator of treatment assignment on the left hand side and covariates at right.
<code>data</code>	A data frame in which <code>fm1a</code> and <code>strata</code> are to be evaluated.
<code>strata</code>	A list of right-hand-side-only formulas containing the factor(s) identifying the strata, with NULL entries interpreted as no stratification; or a factor with length equal to the number of rows in <code>data</code> ; or a data frame of such factors. See below for examples.
<code>unit.weights</code>	Per-unit weight, or 0 if unit does not meet condition specified by <code>subset</code> argument. If there are clusters, the cluster weight is the sum of unit weights of elements within the cluster. Within each stratum, unit weights will be normalized to sum to the number of clusters in the stratum.
<code>stratum.weights</code>	Function returning non-negative weight for each stratum; see details.
<code>subset</code>	Optional: condition or vector specifying a subset of observations to be permitted to have positive unit weights.
<code>include.NA.flags</code>	Present item missingness comparisons as well as covariates themselves?
<code>covariate.scales</code>	covariate dispersion estimates to use as denominators of <code>std.diffs</code> (optional).
<code>post.alignment.transform</code>	Optional transformation applied to covariates just after their stratum means are subtracted off. Should accept a vector of weights as its second argument.
<code>inferentials.calculator</code>	Function; calculates ‘inferential’ statistics. (Not currently intended for use by end-users.)
<code>p.adjust.method</code>	Method of p-value adjustment for the univariate tests. See the p.adjust function for available methods. By default the "holm" method is used.

Details

Given a grouping variable (treatment assignment, exposure status, etc) and variables on which to compare the groups, compare averages across groups and test hypothesis of no selection into groups on the basis of that variable. The multivariate test is the method of combined differences discussed by Hansen and Bowers (2008, Statist. Sci.), a variant of Hotelling’s T-squared test; the univariate tests are presented with multiplicity adjustments, the details of which can be controlled by the user. Clustering, weighting and/or stratification variables can be provided, and are addressed by the tests. The function assembles various univariate descriptive statistics for the groups to be compared: (weighted) means of treatment and control groups; differences of these (adjusted differences); and

adjusted differences as multiples of a pooled s.d. of the variable in the treatment and control groups (standard differences). Pooled s.d.s are calculated with weights but without attention to clustering, and ordinarily without attention to stratification. (If the user does not request unstratified comparisons, overriding the default setting, then pooled s.d.s are calculated with weights corresponding to the first stratification for which comparison is requested. In this case as in the default setting, the same pooled s.d.s are used for standardization under each stratification considered. This facilitates comparison of standard differences across stratification schemes.) Means are contrasted separately for each provided stratifying factor and, by default, for the unstratified comparison, in each case with weights reflecting a standardization appropriate to the designated (post-) stratification of the sample. In the case without stratification or clustering, the only weighting used to calculate treatment and control group means is that provided by the user as `unit.weights`; in the absence of such an argument, these means are unweighted. When there are strata, within-stratum means of treatment or of control observations are calculated using `unit.weights`, if provided, and then these are combined across strata according to a ‘effect of treatment on treated’-type weighting scheme. (The function’s `stratum.weights` argument figures in the function’s inferential calculations but not these descriptive calculations.) To figure a stratum’s effect of treatment on treated weight, the sum of all `unit.weights` associated with treatment or control group observations within the stratum is multiplied by the fraction of clusters in that stratum that are associated with the treatment rather than the control condition. (Unless this fraction is 0 or 1, in which case the stratum is downweighted to 0.)

The function also calculates univariate and multivariate inferential statistics, targeting the hypothesis that assignment was random within strata. These calculations also pool `unit.weights`-weighted, within-stratum group means across strata, but the default weighting of strata differs from that of the descriptive calculations. With `stratum.weights=harmonic_times_mean_weight` (the default), each stratum is weighted in proportion to the product of the stratum mean of `unit.weights` and the harmonic mean $1/[(1/a + 1/b)/2] = 2 * a * b / (a + b)$ of the number of treated units (a) and control units (b) in the stratum; this weighting is optimal under certain modeling assumptions (discussed in Kalton 1968 and Hansen and Bowers 2008, Sections 3.2 and 5). The multivariate assessment is based on a Mahalanobis-type distance that combines each of the univariate mean differences while accounting for correlations among them. It’s similar to the Hotelling’s T-squared statistic, except standardized using a permutation covariance. See Hansen and Bowers (2008).

In contrast to the earlier function `xBalance` that it is intended to replace, `balanceTest` accepts only binary assignment variables (for now).

`stratum.weights` must be a function of a single argument, a data frame containing the variables in `data` and additionally `Tx.grp`, `stratum.code`, and `unit.weights`, returning a named numeric vector of non-negative weights identified by stratum. (For an example, enter `getFromNamespace("harmonic", "RIttools")`.) the data `stratum.weights` function.

If the stratifying factor has NAs, these cases are dropped. On the other hand, if NAs in a covariate are found then those observations are dropped for descriptive calculations and "imputed" to the stratum mean of the variable for inferential calculations. When covariate values are dropped due to missingness, proportions of observations not missing on that variable are recorded and returned. The printed output presents non-missing proportions alongside of the variables themselves, distinguishing the former by placing them at the bottom of the list and enclosing the variable’s name in parentheses. If a variable shares a missingness pattern with other another variable, its missingness information may be labeled with the name of the other variable in the output.

Value

An object of class `c("balancetest", "xbal", "list")`. Several methods are inherited from the "xbal" class returned by `xBalance` function.

Note

Evidence pertaining to the hypothesis that a treatment variable is not associated with differences in covariate values is assessed by comparing the differences of means, without standardization, to their distributions under hypothetical shuffles of the treatment variable, a permutation or randomization distribution. For the unstratified comparison, this reference distribution consists of differences as the treatment assignments of clusters are freely permuted. For stratified comparisons, the reference distributions describes re-randomizations of this type performed separately in each stratum. Significance assessments are based on large-sample approximations to these reference distributions.

`balanceTest.make.stratwts`

balanceTest helper function

Description

Makes strata weights

Usage

```
balanceTest.make.stratwts(stratum.weights, ss.df, zz, data, normalize.weights)
```

Arguments

<code>stratum.weights</code>	Weights
<code>ss.df</code>	df.
<code>zz</code>	treatment
<code>data</code>	data
<code>normalize.weights</code>	weights

Value

list

balanceTestEngine	<i>xBalance helper function</i>
-------------------	---------------------------------

Description

Make engine

Usage

```
balanceTestEngine(  
  ss,  
  zz,  
  mm,  
  report,  
  swt,  
  s.p,  
  normalize.weights,  
  zzname,  
  post.align.trans,  
  p.adjust.method  
)
```

Arguments

ss	ss
zz	zz
mm	mm
report	report
swt	swt
s.p	s.p
normalize.weights	normalize.weights
zzname	zzname
post.align.trans	post.align.trans
p.adjust.method	Method to adjust P.

Value

List

flatten.xbalresult	<i>Flattens xBalance output.</i>
--------------------	----------------------------------

Description

Details...

Usage

```
flatten.xbalresult(  
  x,  
  show.signif.stars = getOption("show.signif.stars"),  
  show.pvals = !show.signif.stars,  
  ...  
)
```

Arguments

x	x
show.signif.stars	Should signif stars be shown?
show.pvals	Should p-val's be shown?
...	Ignored

Value

Structure

formula.xbal	<i>Returns formula attribute of an xbal object.</i>
--------------	---

Description

Returns formula attribute of an xbal object.

Usage

```
## S3 method for class 'xbal'  
formula(x, ...)
```

Arguments

x	An xbal object.
...	Ignored.

Value

The formula corresponding to `xbal`.

<code>gramian_reduction</code>	<i>Helper function to <code>slm_fit_csr</code></i>
--------------------------------	--

Description

This function generates a matrix that can be used to reduce the dimensions of $x'x$ and xy such that positive definiteness is ensured and more practically, that `SparseM::chol` will work

Usage

```
gramian_reduction(zeroes)
```

Arguments

`zeroes` logical vector indicating which entries of the diagonal of $x'x$ are zeroes.

Value

SparseM matrix that will reduce the dimension of $x'x$ and xy

<code>makePval</code>	<i>Get p-value for Z-stats</i>
-----------------------	--------------------------------

Description

Get p-value for Z-stats

Usage

```
makePval(zs)
```

Arguments

`zs` A Z-statistic.

Value

A P-value

naImpute	<i>Impute NA's</i>
----------	--------------------

Description

Function used to fill NAs with imputation values, while adding NA flags to the data.

Usage

```
naImpute(FMLA, DATA, impfn = median, na.rm = TRUE, include.NA.flags = TRUE)
```

Arguments

FMLA	Formula
DATA	Data
impfn	Function for imputing.
na.rm	What to do with NA's
include.NA.flags	Should NA flags be included

Value

Structure

nuclearplants	<i>Nuclear Power Station Construction Data</i>
---------------	--

Description

The data relate to the construction of 32 light water reactor (LWR) plants constructed in the U.S.A in the late 1960's and early 1970's. The data was collected with the aim of predicting the cost of construction of further LWR plants. 6 of the power plants had partial turnkey guarantees and it is possible that, for these plants, some manufacturers' subsidies may be hidden in the quoted capital costs.

Usage

```
nuclearplants
```

Format

A data frame with 32 rows and 11 columns

- cost: The capital cost of construction in millions of dollars adjusted to 1976 base.
- date: The date on which the construction permit was issued. The data are measured in years since January 1 1990 to the nearest month.
- t1: The time between application for and issue of the construction permit.
- t2: The time between issue of operating license and construction permit.
- cap: The net capacity of the power plant (MWe).
- pr: A binary variable where 1 indicates the prior existence of a LWR plant at the same site.
- ne: A binary variable where 1 indicates that the plant was constructed in the north-east region of the U.S.A.
- ct: A binary variable where 1 indicates the use of a cooling tower in the plant.
- bw: A binary variable where 1 indicates that the nuclear steam supply system was manufactured by Babcock-Wilcox.
- cum.n: The cumulative number of power plants constructed by each architect-engineer.
- pt: A binary variable where 1 indicates those plants with partial turnkey guarantees.

Source

The data were obtained from the boot package, for which they were in turn taken from Cox and Snell (1981). Although the data themselves are the same as those in the nuclear data frame in the boot package, the row names of the data frame have been changed. (The new row names were selected to ease certain demonstrations in optmatch.)

This documentation page is also adapted from the boot package, written by Angelo Canty and ported to R by Brian Ripley.

References

Cox, D.R. and Snell, E.J. (1981) *Applied Statistics: Principles and Examples*. Chapman and Hall.

plot.balancetest

Plot of balance across multiple strata

Description

The plot allows a quick visual comparison of the effect of different stratification designs on the comparability of different variables. This is not a replacement for the omnibus statistical test reported as part of [print.xbal](#). This plot does allow the analyst an easy way to identify variables that might be the primary culprits of overall imbalances and/or a way to assess whether certain important co-variables might be imbalanced even if the omnibus test reports that the stratification overall produces balance.

Usage

```
## S3 method for class 'balancetest'
plot(
  x,
  xlab = "Standardized Differences",
  statistic = "std.diff",
  absolute = FALSE,
  strata.labels = NULL,
  variable.labels = NULL,
  groups = NULL,
  ...
)
```

Arguments

<code>x</code>	An object returned by xBalance
<code>xlab</code>	The label for the x-axis of the plot
<code>statistic</code>	The statistic to plot. The default choice of standardized difference is a good choice as it will have roughly the same scale for all plotted variables.
<code>absolute</code>	Convert the results to the absolute value of the statistic.
<code>strata.labels</code>	A named vector of the from <code>c(strata1 = "Strata Label 1", ...)</code> that maps the stratification schemes to textual labels.
<code>variable.labels</code>	A named vector of the from <code>c(var1 = "Var Label1", ...)</code> that maps the variables to textual labels.
<code>groups</code>	A vector of group names for each variable in <code>x\$results</code> . By default, factor level variables will be grouped.
<code>...</code>	additional arguments to pass to balanceplot

Details

By default all variables and all strata are plotted. The scope of the plot can be reduced by using the [subset.xbal](#) function to make a smaller `xbal` object with only the desired variables or strata.

[balanceTest](#) can produce several different summary statistics for each variable, any of which can serve as the data for this plot. By default, the standardized differences between treated and control units makes a good choice as all variables are on the same scale. Other statistics can be selected using the `statistic` argument.

The result of this function is a [ggplot](#) object. Most display of the plot can be manipulated using additional commands appended to the plot option. For example, the entire theme of the plot can be changed to black and white using `plot(b) + theme_bw()`, where `b` is the result of a call to [balanceTest](#). The points on the plot are known as "values", so colors or symbols used for each strata can be updated using the [scale_color_manual](#) function. For example, `plot(b) + scale_color_manual(values = c('red', 'green', 'blue'))` for a balance test of three stratification variables.

Value

A ggplot2 object that can be further manipulated (e.g., to set the colors or text).

See Also

[balanceTest](#), [ggplot](#)

plot.xbal

Plot of balance across multiple strata

Description

The plot allows a quick visual comparison of the effect of different stratification designs on the comparability of different variables. This is not a replacement for the omnibus statistical test reported as part of [print.xbal](#). This plot does allow the analyst an easy way to identify variables that might be the primary culprits of overall imbalances and/or a way to assess whether certain important co-variables might be imbalanced even if the omnibus test reports that the stratification overall produces balance.

Usage

```
## S3 method for class 'xbal'
plot(
  x,
  xlab = "Standardized Differences",
  statistic = "std.diff",
  absolute = FALSE,
  strata.labels = NULL,
  variable.labels = NULL,
  groups = NULL,
  ggplot = FALSE,
  ...
)
```

Arguments

x	An object returned by xBalance
xlab	The label for the x-axis of the plot
statistic	The statistic to plot. The default choice of standardized difference is a good choice as it will have roughly the same scale for all plotted variables.
absolute	Convert the results to the absolute value of the statistic.
strata.labels	A named vector of the from <code>c(strata1 = "Strata Label 1", ...)</code> that maps the stratification schemes to textual labels.
variable.labels	A named vector of the from <code>c(var1 = "Var Label1", ...)</code> that maps the variables to textual labels.

```
strata.labels = c("--" = "Raw Data", "pt" = "Partial Turn-key"),
absolute = TRUE,
groups = c("Group A", "Group A", "Group A", "Group B",
           "Group B", "Group B", "Group A", "Group B"))
```

print.xbal

*Printing xBalance and balanceTest Objects***Description**

A print method for balance test objects produced by xBalance and balanceTest.

Usage

```
## S3 method for class 'xbal'
print(
  x,
  which.strata = dimnames(x$results)[["strata"]],
  which.stats = dimnames(x$results)[["stat"]],
  which.vars = dimnames(x$results)[["vars"]],
  print.overall = TRUE,
  digits = NULL,
  printme = TRUE,
  show.signif.stars = getOption("show.signif.stars"),
  show.pvals = !show.signif.stars,
  horizontal = TRUE,
  report = NULL,
  ...
)
```

Arguments

x	An object of class "xbal" which is the result of a call to xBalance.
which.strata	The stratification candidates to include in the printout. Default is all.
which.stats	The test statistics to include. Default is all those requested from the call to xBalance.
which.vars	The variables for which test information should be displayed. Default is all.
print.overall	Should the omnibus test be reported? Default is TRUE.
digits	To how many digits should the results be displayed? Default is <code>max(2, getOptions("digits")-4)</code> .
printme	Print the table to the console? Default is TRUE.
show.signif.stars	Use stars to indicate z-statistics larger than conventional thresholds. Default is TRUE.
show.pvals	Instead of stars, use p-values to summarize the information in the z-statistics. Default is FALSE.

<code>horizontal</code>	Display the results for different candidate stratifications side-by-side (Default, TRUE), or as a list for each stratification (FALSE).
<code>report</code>	What to report.
<code>...</code>	Other arguments. Not currently used.

Value

variable The formatted table of variable-by-variable statistics for each stratification.

overalltable If the overall Chi-squared statistic is requested, a formatted version of that table is returned.

  data = nuclearplants)

print(xb1)

print(xb1, show.pvals = TRUE)

print(xb1, horizontal = FALSE)

## The following doesn't work yet.
## Not run: print(xb1, which.vars=c("date","t1"),
  which.stats=c("adj.means","z.scores","p.values"))
## End(Not run)

## The following example prints the adjusted means
## labeled as "treatmentvar=0" and "treatmentvar=1" using the
## formula provided to xBalance().

# This is erroring with the change to devtools, FIXME
## Not run: print(xb1,
  which.vars = c("date", "t1"),
  which.stats = c("pr=0", "pr=1", "z", "p"))
## End(Not run)

## Only printing out a specific stratification factor
xb2 <- balanceTest(pr~ date + t1 + t2 + cap + ne + ct + bw + cum.n + strata(pt),
  data = nuclearplants)

print(xb2, which.strata = "pt")
```

scale.DesignOptions	<i>Scale DesignOptions</i>
---------------------	----------------------------

Description

Scale DesignOptions

Usage

```
## S3 method for class 'DesignOptions'  
scale(x, center = TRUE, scale = TRUE)
```

Arguments

x	DesignOptions object
center	logical, or a function acceptable as post.alignment.transformarg of alignDesignsByStrata()
scale	logical, whether to scale

slm_fit_csr	<i>SparseM::slm.fit.csr, made tolerant to faults that recur in Rltools</i>
-------------	--

Description

[SparseM's slm.fit.csr()] expects a full-rank x that's not just a column of 1s. This variant somewhat relaxes these expectations.

Usage

```
slm_fit_csr(x, y, ...)
```

Arguments

x	As slm.fit.csr
y	As slm.fit.csr
...	As slm.fit.csr

Details

'slm.fit.csr' has a bug for intercept only models (admittedly, these are generally a little silly to be done as a sparse matrix), but in order to avoid duplicate code, if everything is in a single strata, we use the intercept only model.

This function's expectation of x is that either it has full column rank, or the reduced submatrix of x that excludes all-zero columns has full column rank. (When this expectation is not met, it's likely that [SparseM::chol()] will fail, causing this function to error; the error messages won't necessarily suggest this.) The positions of nonzero x-columns (ie columns with nonzero entries) are returns as the value of 'gramian_reduction_index', while 'chol' is the Cholesky decomposition of that submatrix's Gramian.

Value

A list consisting of:

coefficients	coefficients
chol	Cholesky factor of Gramian matrix $x'x$
residuals	residuals
fitted	fitted values
df.residual	degrees of freedom
gramian_reduction_index	Column indices identifying reduction of x matrix of which Gramian is taken; see Details

SparseM_solve	<i>Helper function to slm_fit_csr</i>
---------------	---------------------------------------

Description

This function performs some checks and takes action to ensure positive definiteness of matrices passed to SparseM functions.

Usage

SparseM_solve(x, y, ...)

Arguments

x	A slm.fit.csr
y	A slm.fit.csr
...	A slm.fit.csr

Value

list containing coefficients (vector or matrix), the Cholesky decomposition (of class matrix.csr.chol), and a vector specifying the indices of which values on the diagonal of $x'x$ are nonzero. These are named "coef", "chol" and "gramian_reduction_index", respectively.

StratumWeightedDesignOptions-class
<i>Stratum Weighted DesignOptions</i>

Description

Stratum Weighted DesignOptions

Slots

Sweights stratum weights

subset.xbal	<i>Select variables, strata, and statistics from a xbal or balancetest object</i>
-------------	---

Description

If any of the arguments are not specified, all the of relevant items are included.

Usage

```
## S3 method for class 'xbal'
subset(x, vars = NULL, strata = NULL, stats = NULL, tests = NULL, ...)
```

Arguments

x	The xbal object, the result of a call to xBalance or balanceTest
vars	The variable names to select.
strata	The strata names to select.
stats	The names of the variable level statistics to select.
tests	The names of the group level tests to select.
...	Other arguments (ignored)

Value

A xbal object with just the appropriate items selected.

tidy.xbal	<code>broom::tidy()/glance()</code> <i>methods for balanceTest() results</i>
-----------	--

Description

Portion out the value of a [balanceTest\(\)](#) call in a manner consistent with assumptions of the broom package.

Usage

```
tidy.xbal(
  x,
  strata = dimnames(x[["results"]])[["strata"]][1],
  varnames_crosswalk = c(z = "statistic", p = "p.value"),
  format = FALSE,
  digits = max(2, getOption("digits") - 4),
  ...
)

glance.xbal(x, strata = dimnames(x[["results"]])[["strata"]][1], ...)
```

Arguments

<code>x</code>	object of class "xbal", result of <code>balanceTest()</code> or <code>xBalance()</code>
<code>strata</code>	which stratification to return info about? Defaults to last one specified in originating function call (which appears first in the xbal array).
<code>varnames_crosswalk</code>	character vector of new names for xbal columns, named by the xbal column
<code>format</code>	if true, apply <code>[RIttools:::original_units_var_formatter()]</code> to suitable sub-array en route
<code>digits</code>	passed to <code>[RIttools:::original_units_var_formatter()]</code>
<code>...</code>	Additional arguments passed to <code>[RIttools:::original_units_var_formatter()]</code>

Details

`tidy.xbal()` gives per-variable statistics whereas `glance.xbal()` extracts combined-difference related calculations. In both cases one has to specify which stratification one wants statistics about, as xbal objects can store info about several stratifications. `tidy.xbal()` has a parameter `varnames_crosswalk` not shared with `glance.xbal()`. It should be a named character vector, the elements of which give names of columns to be returned and the names of which correspond to columns of xbal objects' 'results' entry. Its ordering dictates the order of the result. The default value translates between conventional xbal column names and broom package conventional names.

vars variable name

Control mean of LHS variable = 0 group

Treatment mean of LHS variable = 1 group

adj.diff T - C diff w/ direct standardization for strata if applicable

std.diff adj.diff/pooled.sd

pooled.sd pooled SD

statistic z column from the xbal object

p.value p column from the xbal object

Additional parameters beyond those listed here are ignored (at this time).

Value

data frame composed of: for `[RIttools::tidy()]`, a column of variable labels (`vars`) and additional columns of balance-related stats; for `[RIttools::glance()]`, scalars describing a combined differences test, if found, and otherwise NULL.

withOptions	<i>Safe way to temporarily override options()</i>
-------------	---

Description

Safe way to temporarily override options()

Usage

```
withOptions(optionsToChange, fun)
```

Arguments

optionsToChange	Which options.
fun	Function to run with new options.

Value

Result of fun.

xBalance	<i>Standardized Differences for Stratified Comparisons</i>
----------	--

Description

Given covariates, a treatment variable, and a stratifying factor, calculates standardized mean differences along each covariate, with and without the stratification and tests for conditional independence of the treatment variable and the covariates within strata.

Usage

```
xBalance(
  fmla,
  strata = list(unstrat = NULL),
  data,
  report = c("std.diffs", "z.scores", "adj.means", "adj.mean.diffs",
    "adj.mean.diffs.null.sd", "chisquare.test", "p.values", "all")[1:2],
  stratum.weights = harmonic,
  na.rm = FALSE,
  covariate.scaling = NULL,
  normalize.weights = TRUE,
  impfn = median,
  post.alignment.transform = NULL,
  pseudoinversion_tol = .Machine$double.eps
)
```

Arguments

<code>fmla</code>	A formula containing an indicator of treatment assignment on the left hand side and covariates at right.
<code>strata</code>	A list of right-hand-side-only formulas containing the factor(s) identifying the strata, with NULL entries interpreted as no stratification; or a factor with length equal to the number of rows in data; or a data frame of such factors. See below for examples.
<code>data</code>	A data frame in which <code>fmla</code> and <code>strata</code> are to be evaluated.
<code>report</code>	Character vector listing measures to report for each stratification; a subset of <code>c("adj.means", "adj.mean.diffs", "adj.mean.diffs.null.sd", "chisquare.test", "std.diffs", "z.scores", "p.values", "all")</code> . P-values reported are two-sided for the null-hypothesis of no effect. The option "all" requests all measures.
<code>stratum.weights</code>	Weights to be applied when aggregating across strata specified by <code>strata</code> , defaulting to weights proportional to the harmonic mean of treatment and control group sizes within strata. This can be either a function used to calculate the weights or the weights themselves; if <code>strata</code> is a data frame, then it can be such a function, a list of such functions, or a data frame of stratum weighting schemes corresponding to the different stratifying factors of <code>strata</code> . See details.
<code>na.rm</code>	Whether to remove rows with NAs on any variables mentioned on the RHS of <code>fmla</code> (i.e. listwise deletion). Defaults to FALSE, wherein rows aren't deleted but for each variable with NAs a missing-data indicator variable is added to the variables on which balance is calculated and medians are imputed for the variable with missing data (in Rltools versions 0.1-9 and before the default imputation was the mean, in Rltools versions 0.1-11 and henceforth the default is the median). See the example below.
<code>covariate.scaling</code>	A scale factor to apply to covariates in calculating <code>std.diffs</code> . If NULL, <code>xBalance</code> pools standard deviations of each variable in the treatment and control group (defining these groups according to whether the LHS of formula is greater than or equal to 0). Also, see details.
<code>normalize.weights</code>	If TRUE, then stratum weights are normalized so as to sum to 1. Defaults to TRUE.
<code>impfn</code>	A function to impute missing values when <code>na.rm=FALSE</code> . Currently <code>median</code> . To impute means use <code>mean.default</code> .
<code>post.alignment.transform</code>	Optional transformation applied to covariates just after their stratum means are subtracted off.
<code>pseudoinversion_tol</code>	The function uses a singular value decomposition to invert a covariance matrix. Singular values less than this tolerance will be treated as zero.

Details

Note: the newer `balanceTest` function provides the same functionality as `xBalance` with additional support for clustered designs. While there are no plans to deprecate `xBalance`, users are encouraged to use `balanceTest` going forward.

In the unstratified case, the standardized difference of covariate means is the mean in the treatment group minus the mean in the control group, divided by the S.D. (standard deviation) in the same variable estimated by pooling treatment and control group S.D.s on the same variable. In the stratified case, the denominator of the standardized difference remains the same but the numerator is a weighted average of within-stratum differences in means on the covariate. By default, each stratum is weighted in proportion to the harmonic mean $1/[(1/a + 1/b)/2] = 2 * a * b / (a + b)$ of the number of treated units (a) and control units (b) in the stratum; this weighting is optimal under certain modeling assumptions (discussed in Kalton 1968, Hansen and Bowers 2008). This weighting can be modified using the `stratum.weights` argument; see below.

When the treatment variable, the variable specified by the left-hand side of `fmla`, is not binary, `xBalance` calculates the covariates' regressions on the treatment variable, in the stratified case pooling these regressions across strata using weights that default to the stratum-wise sum of squared deviations of the treatment variable from its stratum mean. (Applied to binary treatment variables, this recipe gives the same result as the one given above.) In the numerator of the standardized difference, we get a "pooled S.D." from separating units into two groups, one in which the treatment variable is 0 or less and another in which it is positive. If `report` includes "adj.means", covariate means for the former of these groups are reported, along with the sums of these means and the covariates' regressions on either the treatment variable, in the unstratified ("pre") case, or the treatment variable and the strata, in the stratified ("post") case.

`stratum.weights` can be either a function or a numeric vector of weights. If it is a numeric vector, it should be non-negative and it should have stratum names as its names. (i.e., its names should be equal to the levels of the factor specified by `strata`.) If it is a function, it should accept one argument, a data frame containing the variables in `data` and additionally `Tx.grp` and `stratum.code`, and return a vector of non-negative weights with stratum codes as names; for an example, do `getFromNamespace("harmonic", "RIttools")`.

If `covariate.scaling` is not `NULL`, no scaling is applied. This behavior is likely to change in future versions. (If you want no scaling, set `covariate.scaling=1`, as this is likely to retain this meaning in the future.)

`adj.mean.diffs.null.sd` returns the standard deviation of the Normal approximated randomization distribution of the strata-adjusted difference of means under the strict null of no effect.

Value

An object of class `c("xbal", "list")`. There are `plot`, `print`, and `xtable` methods for class "xbal"; the `print` method is demonstrated in the examples.

Note

Evidence pertaining to the hypothesis that a treatment variable is not associated with differences in covariate values is assessed by comparing the differences of means (or regression coefficients), without standardization, to their distributions under hypothetical shuffles of the treatment variable, a permutation or randomization distribution. For the unstratified comparison, this reference distribution consists of differences (more generally, regression coefficients) when the treatment variable is permuted without regard to strata. For the stratified comparison, the reference distribution is determined by randomly permuting the treatment variable within strata, then re-calculating the treatment-control differences (regressions of each covariate on the permuted treatment variable). Significance assessments are based on the large-sample Normal approximation to these reference distributions.

         post.alignment.transform=rank)

```

xtable.xbal

An xtable method for xbal and balancetest objects

Description

This function uses the [xtable](#) package framework to display the results of a call to [balanceTest](#) in LaTeX format. At the moment, it ignores the omnibus chi-squared test information.

Usage

```

## S3 method for class 'xbal'
xtable(
  x,
  caption = NULL,
  label = NULL,
  align = c("l", rep("r", ncol(xvardef))),
  digits = 2,
  display = NULL,
  auto = FALSE,
  col.labels = NULL,
  ...
)

```

Arguments

<code>x</code>	An object resulting from a call to <code>balanceTest</code> or <code>xBalance</code> .
<code>caption</code>	See <code>xtable</code> .
<code>label</code>	See <code>xtable</code> .
<code>align</code>	See <code>xtable</code> . Our default (as of version 0.1-7) is right-aligned columns; for decimal aligned columns, see details, below.
<code>digits</code>	See <code>xtable</code> . Default is 2.
<code>display</code>	See <code>xtable</code> .
<code>auto</code>	See <code>xtable</code> .
<code>col.labels</code>	Labels for the columns (the test statistics). Default are come from the call to <code>print.xbal</code> .
<code>...</code>	Other arguments to <code>print.xbal</code> .

Details

The resulting LaTeX will present one row for each variable in the formula originally passed to `balanceTest`, using the variable name used in the original formula. If you wish to have reader friendly labels instead of the original variables names, see the code examples below.

To get decimal aligned columns, specify `align=c("l",rep(".", <ncols>))`, where `<ncols>` is the number of columns to be printed, in your call to `xtable`. Then use the `dcolumn` package and define `'.''` within LaTeX: add the lines `\usepackage{dcolumn}` and `\newcolumnntype{.}{D{.}{.}{2.2}}` to your LaTeX document's preamble.

Value

This function produces an `xtable` object which can then be printed with the appropriate print method (see `print.xtable`).

Examples

```
data(nuclearplants)
require(xtable)

# Test balance on a variety of variables, with the 'pr' factor
# indicating which sites are control and treatment units, with
# stratification by the 'pt' factor to group similar sites
xb1 <- balanceTest(pr ~ date + t1 + t2 + cap + ne + ct + bw + cum.n + strata(pt),
  data = nuclearplants)

xb1.xtab <- xtable(xb1) # This table has right aligned columns

# Add user friendly names in the final table
rownames(xb1.xtab) <- c("Date", "Application to Contruction Time",
  "License to Construction Time", "Net Capacity", "Northeast Region", "Cooling Tower",
  "Babcock-Wilcox Steam", "Cumlative Plants")

print(xb1.xtab,
```

```

add.to.row = attr(xb1.xtab, "latex.add.to.row"),
hline.after = c(0, nrow(xb1.xtab)),
sanitize.text.function = function(x){x},
floating = TRUE,
floating.environment = "sidewaystable")

```

ym_long

ASSIST Trial Data from Yudkin and Moher 2001

Description

The ASSIST Trial baseline data from Yudkin and Moher 2001 consist of 21 general practices containing 2142 patients used for the design of a randomized trial which assigned to three treatments aiming to compare methods of preventing coronary heart disease. We have expanded the aggregated data from the practice level to the individual level and added a simulated randomized treatment variable.

Usage

ym_long

Format

A data frame with 2142 rows and 9 columns

- practice: Identifier for the practice
- id: Identifier for patients
- n_practice: Number of patients with CHD in the practice
- assessed: Whether a patient was coded as "adequately assessed" (the outcome of the study, measured here at baseline).
- aspirin: Whether a patient was treated with aspirin at baseline.
- hypo: Whether a patient was treated with hypotensives at baseline.
- lipid: Whether patient was treated with lipid-lowering drugs at baseline.
- assess_strata: Strata of the practice defined by the proportion of people adequately assessed at baseline (three strata, following Yudkin and Moher 2001).
- trt: A simulated binary treatment, assigned at random at the practice level within levels of assess_strata.

Source

The data come from Table II on page 345 of Yudkin and Moher 2001, *Statistics in Medicine*.
